Keywords: Luminescence Defects Ce³⁺ Multicomponent garnets Single crystals Scintillators

ABSTRACT

Luminescence characteristics of Ce^{3+} - doped $Gd_3Ga_xAl_{5-x}O_{12}$ single crystals with different Ga contents (x = 1, 2, 3, 4, 5) are studied in the 9–500 K temperature range. The spectra of the afterglow, photoluminescence, radioluminescence, and thermally stimulated luminescence (TSL) of each crystal coincide. The increase of the Ga content results in the high-energy shift of the spectra while the radioluminescence intensity at 9 K remains practically constant up to x = 4. No Ce^{3+} emission is observed in case of x = 5. The total TSL intensity drastically increases, reaches the maximum value around x = 2–3, and then decreases due to the thermal quenching of the Ce^{3+} emission. The TSL glow curve maxima are gradually shifting to lower temperatures, and the dependence of the maxima positions and the corresponding trap depths on the Ga content is close to linear. However, the activation energy of the TSL peaks creation under irradiation of the crystals in the $4f-5d_1$ absorption band of Ce^{3+} decreases drastically with the increasing Ga content (especially in the range of x = 1–2), and this dependence is found to be strongly nonlinear. Possible reasons of the nonlinearity are discussed.

1. Introduction

In recent years, the Ce - doped $Gd_3Ga_xAl_{5-x}O_{12}$ single crystals, ceramics and epitaxial films with different Ga contents (x) were intensively studied as promising scintillator materials for their application in medical imaging because of their extremely high light yield, good energy resolution, relatively high density (6.63 g/cm^3) , fast scintillation response, and high radiation stability and hardness [1-25]. Single crystals of $Gd_3Ga_xAl_{5-x}O_{12}$:Ce prepared by the micro-pulling down method were first reported in Ref. [1]. Their scintillation characteristics were found to depend on the Ga concentration. For the crystal with x=3, the light yield of $\approx 42\,000$ photons/MeV, the dominating decay time of $\approx 53\,$ ns, and the energy resolution of 8.3%@662 keV were obtained. With the decreasing Ga content, the light yield and energy resolution were found to improve, but the decay time increases. The first $Gd_3Ga_3Al_2O_{12}$:Ce single crystal grown by the Czochralski method

with the light yield of 46 000 photons/MeV and energy resolution of 4.9%@662 keV was reported in Ref. [2]. Recently, an extremely high light yield of 58 000 photons/MeV and the best energy resolution of 4.2%@662 keV were obtained for the single crystals of $Gd_3Ga_xAl_{5-x}O_{12}$:Ce with x=2.7 and x=2.4, respectively, also grown by the Czochralski method [11]. Due to these characteristics, $Gd_3Ga_xAl_{5-x}O_{12}$:Ce with x=2-3 was considered as a promising scintillator for the PET application [2].

The systematic photoluminescence study of $Gd_3Ga_xAl_{5-x}O_{12}$:Ce showed that the increasing Ga content results in the high-energy shift of the Ce^{3+} - related $5d_1-4f$ emission band and the lowest-energy $4f-5d_1$ absorption (excitation) band as well as in the low-energy shift of the $4f-5d_2$ excitation band [6,24]. The Stokes shift slightly increases as well. The decrease of both the crystal field strength and the band gap of the host material was reported (see, e.g. [4,6], and references therein). According to [6], the activation energy of thermal quenching of the $5d_1-4f$ emission determined from the temperature dependence of the luminescence decay time decreases linearly from $E_q \approx 0.6$ eV for x=0 to $E_q \approx 0.07$ eV for x=4. The TSL characteristics were studied for $Gd_3Ga_3Al_2O_{12}$:Ce crystals in Refs. [9,10,13], for the $Gd_3Ga_xAl_{5-x}O_{12}$:Ce epitaxial films

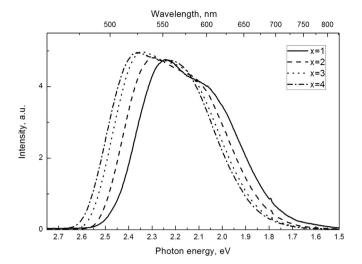

Fig. 1. X-ray excited luminescence spectra of the $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystals with different Ga contents (shown in the legend) measured at the same conditions at $T=9~\rm K$.

with the Ga content varying from x=2.7 to x=3.54, in Ref. [23], and for the $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystal with x=2.83, in Ref. [25], i.e., the x values in the previous studies varied only from 2.7 to 3.54.

In the present work, the characteristics of the photo- and X-ray excited luminescence and TSL of the $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystals with different Ga contents (x = 1, 2, 3, 4, 5) grown by the micro-pulling down method are measured in a wide temperature range (9–500 K) and compared. The aim of this work is to investigate the dependences of these characteristics on the Ga content, to explain the mechanisms of these dependences, and to clarify a possible role of Ga^{3+} ions in the defects formation processes in these scintillation materials.

2. Experimental procedure

Single crystals of $Gd_3Ga_xAl_{5-x}O_{12}$:Ce with the same (0.2 at.%) Ce content and different Ga contents (x = 1, 2, 3, 4, 5) were grown by the micro-pulling down method [1]. Pieces of the grown crystals were crushed and ground into a powder in a mortar. Powder X-ray diffraction (XRD) analysis was carried out in the 2θ range $15^{\circ}-75^{\circ}$ using a RINT Ultima (RIGAKU) diffractometer. Cu K α X-ray source was used, and the accelerating voltage and current were 40 kV and 40 mA, respectively. Quantitative chemical analysis of the crystals for Al, Ce, Y and Gd content along the growth direction was performed by electron probe microanalysis (EPMA; JXA-8621MX, JEOL), for the details see Ref. [1]. Disks of about 1 mm thickness were cut from crystal rods of about 3 mm diameter and polished up to a optical grade.

The steady-state emission and excitation spectra in the

85–500 K temperature range were measured using a setup, consisting of the LOT - ORIEL xenon lamp (150 W), two monochromators (SF - 4 and SPM - 1) and nitrogen cryostat. The luminescence was detected by a photomultiplier (FEU - 39 or FEU - 79) connected with an amplifier and recorder.

The X-ray excited luminescence and afterglow spectra were measured at 9 K after a crystal was irradiated with the X-ray tube (40 kV, 15 mA) for 10 min to achieve the intensity saturation. The luminescence was detected using Andor Shamrock B-303i spectrograph coupled to Andor DU-401A-BV CCD camera.

TSL glow curves I_{TSL}(T) were measured with a heating rate of 0.2 K/s at two different setups. At the first setup, the TSL glow curves were measured in the 85-500 K temperature range after selective ultraviolet (UV) irradiation of the crystals at different temperatures T_{irr} with different irradiation photon energies E_{irr}. A crystal located in a nitrogen cryostat was irradiated with the LOT -ORIEL xenon lamp (150 W) through a monochromator SF - 4. The spectral width of the monochromator slit did not exceed 5 nm. The TSL glow curves were measured with the monochromator SPM - 1 and detected with the photomultiplier FEU - 39 and recorder. For each TSL glow curve peak, the TSL peak creation spectrum, i.e., the dependence of the maximum TSL intensity (I_{TSL}^{max}) on the irradiation photon energy E_{irr}, was measured. From the dependence of the maximum TSL intensity (I_{TSL}^{max}) on the irradiation temperature T_{irr} , the activation energy E_a for the TSL peak creation was determined. To determine the trap depth E_t corresponding to each TSL peak, the partial cleaning method was used (for more details, see, e.g. [26]. and references therein). The crystal, irradiated at the temperature T_{irr} , was cooled down to 85 K, heated up to a temperature T_{stop} , then quickly cooled down to 85 K and the TSL glow curve was recorded. In the next cycle, the same procedure was repeated for the different temperature T_{stop} , etc. From the slope of the $ln(I_{TSL})$ as a function of the reverse temperature (1/T), the E_t value was calculated.

At the second setup, the TSL spectra and glow curves were measured in the 9–300 K temperature range after X-ray irradiation of the crystals with the X-ray tube (40 kV, 15 mA) for 5 min. The luminescence was detected using Andor Shamrock B-303i spectrograph coupled to Andor DU-40 1A-BV CCD camera. Trap depths were determined using fractional glow technique [27].

3. Experimental results and discussion

The radioluminescence spectra of $Gd_3Ga_xAl_{5-x}O_{12}$:Ce measured at the same conditions at 9 K are shown in Fig. 1. The position of the center of the doublet Ce^{3+} - related emission band (E_{em}) and its full width at half maximum (FWHM) for each crystal are presented in Table 1. It is evident that the emission band is shifting to high energies with the increasing Ga content while the radioluminescence intensity at 9 K remains practically constant up to x=4. No Ce^{3+} emission is observed in case of x=5. The photoluminescence spectra as well as the spectra of the afterglow and low-temperature TSL of each sample coincide with the spectra shown in Fig. 1. The photoluminescence excitation spectrum consists of several bands

Table 1
The position (E_{em}) and FWHM of the X-ray excited luminescence band at 9 K, activation energy E_q of the luminescence thermal quenching obtained in the present work from the I(T) dependences measured in the T > 430 K temperature region and in Ref. [6] from the temperature dependences of the decay times, activation energy E_a of the TSL peaks creation under irradiation in the $4f - 5d_1$ absorption band of Ce^{3+} , and the energy difference E_{dc} between the $5d_1$ level of Ce^{3+} and the bottom of the CB estimated in this work and reported in Ref. [29] for the $Gd_3(Ga,Al)_5O_{12}$:Ce single crystals with different Ga contents.

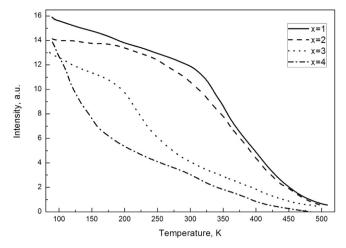

Fig. 2. Temperature dependences of the maximum Ce^{3+} - related luminescence intensity measured under excitation in the maximum of the $4f - 5d_1$ absorption band of Ce^{3+} centers.

arising from the 4f - 5d transitions of Ce^{3+} ions. The dependences of the emission and excitation spectra of the investigated Gd₃Ga_xAl_{5-x}O₁₂:Ce crystals on the Ga content are similar to those reported earlier and explained by the shrinkage of the forbidden gap and changes in the energies of the 5d₁, 5d₂ excited states of Ce³⁺ with respect to the 4f ground state of Ce³⁺ and the bottom of the conduction band (CB) (see, e.g. [4,6,24], and references therein). Temperature dependences of the Ce³⁺ - related photoluminescence intensity (Fig. 2) indicate that the activation energy Eq of the luminescence thermal quenching strongly decreases with the increasing Ga content (see also [6,24]). At the temperature dependence of the 5d₁ - 4f luminescence intensity (I) demonstrated for some crystals in the lnI - 1/T coordinates (Fig. 3), several stages with different activation energies E_q can be observed. The E_q values obtained in the high-temperature range (430-500 K) are shown in Table 1.

After X-ray irradiation of the crystals at 9 K as well as after their UV irradiation at an appropriate temperature in the maximum of the 4f - 5d₂ (around 3.6 eV) or 4f - 5d₁ (around 2.8 eV) absorption band of Ce^{3+} , the Ce^{3+} - related TSL appears due to the creation of the recombining electron centers and the hole Ce^{4+} centers. The TSL glow curves measured for the Ce^{3+} can be a superficient of the Ce^{3+} contents and the hole Ce^{4+} centers.

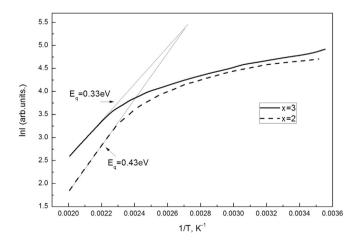

Fig. 3. Some selected temperature dependences of the $5d_1-4f$ luminescence intensity (I) presented the ln I -1/T coordinates and the activation energies E_q of the luminescence thermal quenching in the high-temperature range.

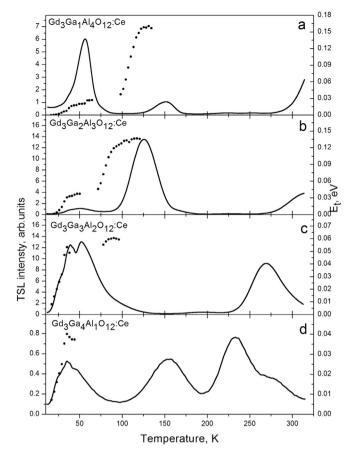

Fig. 4. TSL glow curves measured for the $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystals with different Ga contents after their X-ray irradiation at 9 K (solid lines) and the trap depths E_r corresponding to the lowest-temperature TSL peaks (filled circles).

with different Ga contents are shown in Figs. 4 and 5. For the Gd₃Ga₃Al₂O₁₂:Ce crystal (Figs. 4c and 5c), the TSL glow curve is similar to those obtained in Refs. [9,10,13,25] for analogous crystals grown using the Czochralski technique, however, the intensity ratios of the low-temperature and the high-temperature TSL peaks are strongly different. The TSL peak positions are presented in Table 2. All the TSL glow curve peaks are complex and consist of several components (see also [9,10,13]). This is evident from the comparison of the TSL glow curves measured after the UV irradiation at different temperatures T_{irr} and appears also in the experiments with partial heating. The total TSL intensity increases (\approx 50 times) with the increasing Ga content and reaches the maximum around x = 2 and x = 3, indicating strongly increasing concentration of electron traps in these crystals. In the sample with x = 4, the total TSL intensity decreases by about an order of magnitude due to the thermal quenching of the Ce³⁺ emission (Fig. 2). Due to the same reason, the intensity ratio of the low-temperature and hightemperature TSL peaks presented in Figs. 4 and 5 is also perturbed. No Ce^{3+} - related TSL is observed in the sample with x = 5.

From the TSL data, the parameters of the traps (trap depths E_t and frequency factors f_0) corresponding to each TSL can be determined (Table 2). The dependences of the trap depth E_t on the temperature T_{stop} are presented in Figs. 4 and 5 (filled circles). The presence of the $E_t(T_{stop})$ dependence in the range of a TSL peak is an evidence of its complex structure (see also [10,13]). The positions of the peaks at the TSL glow curve obtained after X-ray irradiation of the crystals at 9 K are found to be independent of the irradiation duration (measured up to $t_{irr}=2$ h). This confirms the first-order

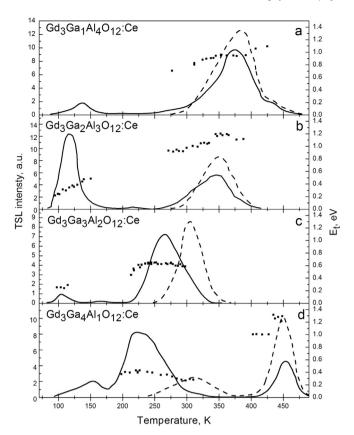

Fig. 5. TSL glow curves measured for the $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystals with different Ga contents after their UV irradiation at 85 K in the $4f-5d_2$ absorption band of Ce^{3+} (solid line) and after irradiation at 295 K in the $4f-5d_1$ absorption band of Ce^{3+} (dashed line) and the corresponding trap depths E_t (filled circles).

Table 2 The TSL peaks positions (T_m) , trap depths (E_t) , and frequency factors (f_0) obtained for the $Gd_3(Ga,Al)_5O_{12}$:Ce single crystals with different Ga contents.

recombination kinetics reported for $Gd_3Ga_3Al_2O_{12}$:Ce in Refs. [9,10,13]. In this case, the frequency factors f_0 can be calculated using the expression

$$f_0 = (\beta E_t / kT_m^2) \exp(E_t / kT_m)$$

where β is the crystal heating rate, k is the Boltzmann factor, and T_m is the maximum position of the considered TSL peak. Due to a complex structure of the TSL peaks, only approximate values of the E_t and f_0 parameters could be obtained. The T_m value is taken as the temperature where the peak position becomes independent of T_{stop} . According to our estimations, T_m values for the main TSL

peaks can be defined with an accuracy of about 2-5 K. The values of E_t are defined with an accuracy of about 5-10%. For the f_0 values, only an order of magnitude can be roughly estimated.

In Fig. 6, the dependences of the higher-temperature TSL peak position (filled triangles) and the corresponding trap depth value E_t (empty circles) on the Ga content are presented. These dependences can be explained by the Ga^{3+} - induced lowering of the CB bottom energy with the increasing Ga content (see, e.g., [4,28]). Both these dependences are found to be close to linear. Similar dependences have been also obtained for some other Ce^{3+} - doped multicomponent garnets (see, e.g., [23,28], and references therein).

The dependences of the TSL peak intensity on the irradiation duration t_{irr} are found to depend on the TSL peak and the crystal irradiation temperature and energy. Some selected dose dependences measured for the $Gd_3Ga_3Al_2O_{12}$:Ce crystal are shown in Fig. 7. A quick saturation of the TSL intensity (curves 1 and 2), probably caused by a close location of the recombining electron and hole centers, is observed also for the 160 K peak in the crystal with x=4 irradiated at 85 K in the $4f-5d_2$ absorption band of Ce^{3+} . The dependence similar to curve 3 in Fig. 7 is observed for the TSL peaks at 342 K and 375 K in the crystals with x=2 and x=1, respectively, irradiated at 85 K in the $4f-5d_2$ absorption band of Ce^{3+} .

From the dependence of the TSL peak intensity on the irradiation temperature T_{irr} presented in the $\ln(I_{TSL})-1/T_{irr}$ coordinates (Fig. 8), the activation energy E_a can be determined for the TSL peaks creation (Table 1). The data obtained indicate that in the crystal with x=1, the $5d_2$ level is located slightly below the conduction band and $E_a\approx 0.07$ eV. Taking into account the $5d_1-5d_2$ energy distance (0.97 eV) which can be obtained from the excitation spectrum of the Ce^{3+} emission in this crystal, the activation energy for the TSL peaks creation under irradiation in the $4f-5d_1$ absorption band of Ce^{3+} is estimated to be $E_a\approx 1.04$ eV. For the crystals with a higher Ga content, the $5d_2$ level is located inside the conduction band.

Usually, the Ce^{3+} luminescence thermal quenching and the appearance of TSL peaks are both explained as a result of the photostimulated electron release from the lowest-energy excited $5d_1$ level of Ce^{3+} into the CB. If this is the case, the values of the activation energies E_q and E_a should be close and correspond to the energy distance between the $5d_1$ excited level of Ce^{3+} and the

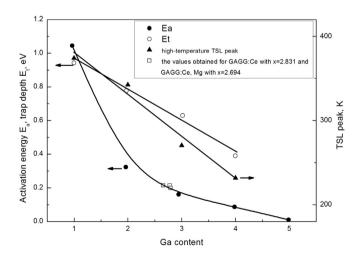

Fig. 6. Dependences of the activation energy E_a of the TSL peaks creation (filled circles), the position of the high-temperature TSL peak (filled triangles), and the corresponding trap depth E_t (empty circles) on the Ga content obtained for the $G_3G_{ax}Al_{s-x}O_{12}$:Ce single crystals. The E_a values obtained in Ref. [25] for the Ce - doped crystal with x=2.831 and for the Ce, Mg co - doped crystal with x=2.694 are shown by empty squares.

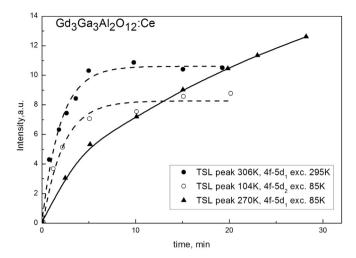

Fig. 7. Dependences of the TSL intensity on the irradiation duration $t_{\rm irr}$ measured for the $Gd_3Ga_3Al_2O_{12}$:Ce single crystal. The selected TSL peaks and irradiation conditions are shown in the legend.

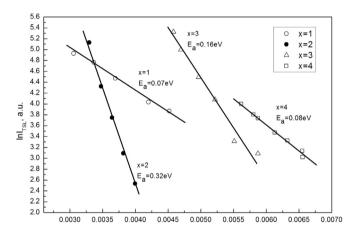

Fig. 8. Dependences of the TSL intensity (I_{TSL}) on the irradiation temperature (T_{irr}) presented in the $ln(I_{TSL}) - 1/T_{irr}$ coordinates and the values of the corresponding activation energies E_a obtained for different $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystals.

bottom of the CB. However, the E_a values differ from the activation energies E_q of the $5d_1-4f$ emission thermal quenching determined both in the present work from the temperature dependences of the maximum emission intensity (see, e.g., Fig. 3) and in Ref. [6], from the temperature dependence of the luminescence decay time (Table 1). It should be noted that the stage with the activation energy $E_q \approx E_a$ could exist in some temperature range but it is not clearly evident among the other stages.

As it is evident from Fig. 6 (filled circles), the E_a dependence on the Ga content is strongly nonlinear. Similar dependence was also obtained in Ref. [23] at the study of the epitaxial films of Ce^{3+} -doped multicomponent (Gd,Lu)₃(Ga,Al)₅O₁₂ garnets with different Ga contents. The E_a values obtained in Ref. [25] for the Ce - doped $Gd_3Ga_xAl_{5-x}O_{12}$ crystal with x=2.83 and for the Ce, Mg - doped crystal with x=2.69 shown in Fig. 6 by empty squares are also close to the E_a values obtained in the present work and in Ref. [23] for the multicomponent garnets with similar Ga content. However, in case the E_a value is equal to the 5d-CB energy distance and the reduction of the E_a value is caused by the Ga^{3+} - induced lowering of the CB bottom energy, the dependence of E_a on the Ga content should be linear, similar to those presented in Fig. 6 for the positions of the TSL peaks and the corresponding trap depths E_t .

The observed peculiarities of the luminescence thermal quenching and photostimulated defects creation processes in the crystals studied can be explained by the presence of additional energy levels located between the $5d_1$ excited level of Ce^{3+} and the bottom of the CB. In this case, thermally stimulated electron transitions from the excited 5d₁ level of Ce³⁺, resulting in the defects creation, can take place not only to the CB but also to these additional defect levels, and E_a can be considered as the energy difference between the 5d₁ level and the defect level (d). In Fig. 9, the positions of the 5d₁ and 5d₂ excited levels of Ce³⁺ with respect to the 4f ground state level and the position of the defect level d with respect to the $5d_1$ level of Ce^{3+} are schematically shown. The approximate position of the CB bottom is presented by dashed line taking into account the data obtained in this work and indicating that (i) in the crystals with x = 1, the E_a value (1.04 eV) corresponds most probably to the energy distance (E_{dc}) between the $5d_1$ level and the bottom of the CB or is close to E_{dc}; (ii) in the crystal with x = 5, the $5d_1$ level lies inside the CB; (iii) the CB bottom energy decreases linearly with the increasing Ga content. The estimated E_{dc} values are shown in Table 1. The dependences of the band gap energy and the positions of the valence band, conduction band, and the energy levels of Ce³⁺ on the Ga content in Gd₃(Ga,Al)₅O₁₂:Ce have been reported, e.g., in Refs. [6,29,30]. The values of Edc determined in Ref. [29] are presented in Table 1. As it is evident from Table 1, the E_{dc} and E_a values are strongly different, and the E_{dc} values estimated in this work are much larger as compared with those reported in Ref. [29].

As the E_a values obtained for the Ce - and Ce, Mg - doped single crystals and for the Ce - doped epitaxial films of the same (or close) Ga content are very close despite strongly different concentrations of intrinsic defects in the samples studied (for more details, see Refs. [23,25]), the additional defect level d cannot arise from the intrinsic defects. Indeed, the concentration of intrinsic electron traps cannot so strongly (about 50 times) increase with the increasing Ga content from x=1 to x=2. Therefore, we suggest that the additional defect levels located below the bottom of the CB can be connected with the Ga^{3+} ions perturbed by the nearest neighboring Ce^{3+} ions.

The trapping of electrons, thermally released from the excited Ce³⁺ levels, by these perturbed Ga³⁺ ions might result in the

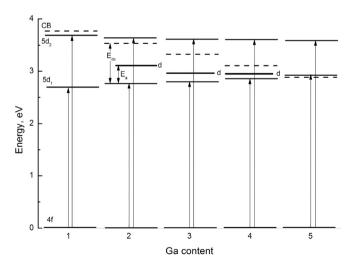

Fig. 9. Positions of the $5d_1$ and $5d_2$ excited levels of Ce^{3+} and the defect level d (solid lines) and the suggested position of the CB bottom (dashed line) with respect to the 4f ground state level of Ce^{3+} in $Gd_3Ga_xAl_{5-x}O_{12}$:Ce single crystals with different Ga contents. The $4f-5d_1$ and $4f-5d_2$ transitions of Ce^{3+} ions are shown by arrows. E_a is the energy difference between the $5d_1$ and d levels. E_{cd} is the estimated energy difference between the $5d_1$ level of Ce^{3+} and the CB bottom.

appearance of the electron Ga^{2+} centers. The energy levels of Ga are placed around the very bottom of the conduction band [28] so that their participation in creation of electron traps can be expected. Stable Ga^{2+} centers with visible emission have been intensively studied, e.g., in alkali halide crystals (see, e.g., [31,32]). However, our attempts to detect their luminescence in the irradiated $Gd_3Ga_xAl_{5-x}O_{12}$:Ce crystals were unsuccessful due to the presence of strong Ce^{3+} - related absorption and emission bands in the considered energy range. The application of EPR for the search of the paramagnetic Ga^{2+} centers in Gd - containing compounds is not possible as well due to a large nuclear spin of Gd^{3+} . Therefore, the origin of the Ga - related defects will be investigated in more detail in the Gd-free and Ce-doped multicomponent garnets.

4. Conclusions

The study of photoluminescence, radioluminescence and TSL characteristics of Ce^{3+} - doped $Gd_3Ga_xAl_{5-x}O_{12}$ (x = 1, 2, 3, 4, 5) single crystals has revealed their strong dependence on the Ga content. The dependences of the maxima positions of the TSL glow curves and the corresponding trap depths Et on the Ga content are found to be close to linear. However, the activation energy E_a of the TSL peaks creation under irradiation of the crystals in the $4f - 5d_1$ absorption band of Ce³⁺ decreases drastically with the increasing Ga content, and this dependence is strongly nonlinear. The conclusion is made that the values of the activation energies for the luminescence thermal quenching (E_q) and the TSL peaks creation (E_a) are not always equal to the energy distance between the 5d₁ excited level of Ce³⁺ and the bottom of the CB. These peculiarities of the Ga - containing multicomponent garnets are suggested to arise from the presence of defect levels located below the bottom of the CB and connected with the Ga³⁺ ions perturbed by the nearest neighboring Ce³⁺ ions. This hypothesis as well as the origin and structure of the Ga-related defects in Gd₃Ga_xAl_{5-x}O₁₂:Ce need further investigations.
